

Lecture 2

SEARCH-BASED PATH FINDING

主讲人 Fei Gao

Ph.D. in Robotics
Hong Kong University of Science and Technology
Assistant Professor, Zhejiang University

Outline

1. Graph Search Basis

2. Dijkstra and A*

3. Jump Point Search

4. Homework

Graph Search Basis

Configuration Space

Configuration Space

- **Robot configuration:** a specification of the positions of all points of the robot
- **Robot degree of freedom (DOF):** The minimum number n of real-valued coordinates needed to represent the robot configuration
- **Robot configuration space:** a n -dim space containing all possible robot configurations, denoted as **C-space**
- **Each robot pose is a point in the C-space**

Configuration Space Obstacle

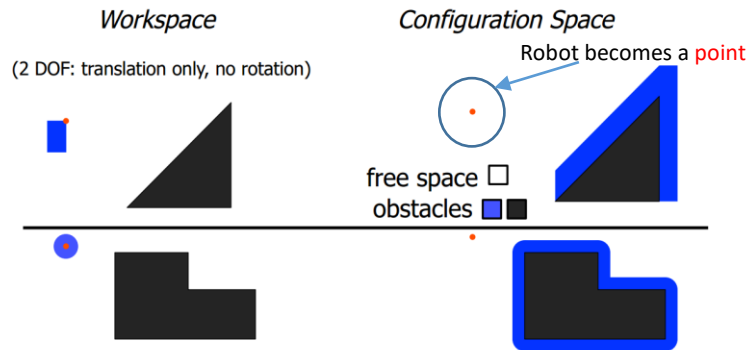

- Planning in workspace
 - Robot has different shape and size
 - Collision detection requires knowing the robot geometry - time consuming and hard

Configuration Space Obstacle

- Planning in configuration space
 - Robot is represented by a point in C-space, e.g. position (a **point** in R^3), pose (a **point** in $SO(3)$), etc.
 - Obstacles need to be represented in configuration space (one-time work prior to motion planning), called configuration space obstacle, or C-obstacle
 - C-space = (C-obstacle) \cup (C-free)
 - The path planning is finding a path between start **point** q_{start} and goal **point** q_{goal} within C-free

Workspace and Configuration Space Obstacle

- In workspace
 - Robot has shape and size (i.e. hard for motion planning)
- In configuration space: C-space
 - Robot is a **point** (i.e. easy for motion planning)
 - Obstacle are represented in C-space prior to motion planning
- Representing an obstacle in C-space can be extremely complicated. So approximated (but more conservative) representations are used in practice.

If we model the robot conservatively as a ball with radius δ_r , then the C-space can be constructed by inflating obstacle at all directions by δ_r .

Graph and Search Method

Search-based Method

Graphs

Graphs have **nodes** and **edges**

Undirected

Weighted

Directed

Search-based Method

- State space graph: a mathematical representation of a **search algorithm**
 - For every search problem, there's a corresponding state space graph
 - Connectivity between nodes in the graph is represented by (directed or undirected) edges

*Ridiculously tiny search graph
for a tiny search problem*

Grid-based graph: use grid as vertices and grid connections as edges

The graph generated by probabilistic roadmap (PRM)

Graph Search Overview

- The search always start from start state X_S
 - Searching the graph produces a search tree
 - Back-tracing a node in the search tree gives us a path from the start state to that node
 - For many problems we can never actually build the whole tree, too large or inefficient – we only want to reach the goal node asap.

Graph Search Overview

- Maintain a **container** to store all the nodes **to be visited**
- The container is initialized with the start state X_s
- Loop
 - **Remove** a node from the container according to some pre-defined score function
 - Visit a node
 - **Expansion**: Obtain all **neighbors** of the node
 - Discover all its neighbors
 - **Push** them (**neighbors**) into the container
- End Loop

Graph Search Overview

- Question 1: When to end the loop?
 - Possible option: End the loop when the container is empty
- Question 2: What if the graph is cyclic?
 - When a node is removed from the container (expanded / visited), it should never be added back to the container again
- Question 3: In what way to remove the right node such that the **goal state can be reached as soon as possible**, which results in less expansion of the graph node.

Graph Traversal

- Breadth First Search (BFS) vs. Depth First Search (DFS)

BFS uses "first in first out"

This is a **queue**

DFS uses "last in first out"

This is a **stack**

Depth First Search (DFS)

- Strategy: remove / expand the deepest node in the container

-

Depth First Search (DFS)

Courtesy: Amit Patel's Introduction to A*, Stanford

Breadth First Search (BFS)

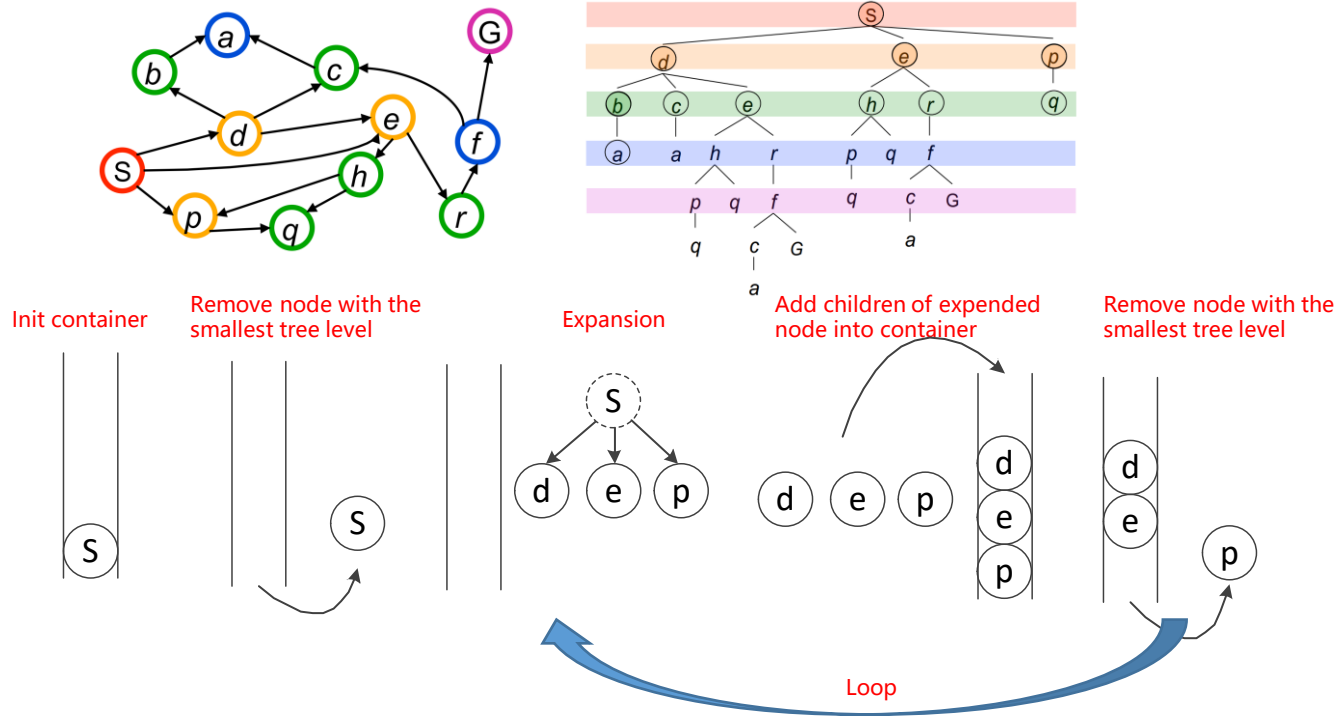

- Strategy: remove / expand the shallowest node in the container

Breadth First Search (BFS)

- Implementation: maintain a first in first out (FIFO) container (i.e. queue)

Breadth First Search (BFS)

Courtesy: Amit Patel's Introduction to A*, Stanford

BFS vs. DFS: which one is useful?

Breadth First Search

Depth First Search

Remember BFS.

Heuristic search

Greedy Best First Search

- BFS and DFS pick the next node off the frontiers based on which was “first in” or “last in”.
- Greedy Best First picks the “best” node according to some rule, called a **heuristic**.
- **Definition:** A heuristic is a **guess** of how close you are to the target.

- A heuristic guides you in the right direction.
- A heuristic should be easy to compute.

- **Euclidean Distance**
- **Manhattan Distance**

Both are approximations for the actual **shortest path**.

Greedy Best First Search

Looks pretty good.

Greedy Best First Search

But with obstacles ...

Costs on Actions

- A practical search problem has a **cost “C”** from a node to its neighbor
 - Length, time, energy, etc.
- When all weight are 1, BFS finds the optimal solution
- For general cases, how to find the **least-cost path** as soon as possible?

Dijkstra and A*

Algorithm Workflow

Dijkstra's Algorithm

- Strategy: expand/visit the node with **cheapest accumulated cost $g(n)$**
 - $g(n)$: The current best estimates of the accumulated cost from the start state to node "n"
 - Update the accumulated costs $g(m)$ for all unexpanded neighbors "m" of node "n"
 - A node that has been expanded/visited is guaranteed to have the smallest cost from the start state

Dijkstra's Algorithm

- Maintain a **priority queue** to store all the nodes to be expanded
- The priority queue is initialized with the start state X_s
- Assign $g(X_s)=0$, and $g(n)=\text{infinite}$ for all other nodes in the graph
- Loop
 - If the queue is empty, return FALSE; break;
 - Remove the node "n" with the lowest $g(n)$ from the priority queue
 - Mark node "n" as expanded
 - If the node "n" is the goal state, return TRUE; break;
 - For all unexpanded neighbors "m" of node "n"
 - If $g(m) = \text{infinite}$
 - $g(m) = g(n) + C_{nm}$
 - Push node "m" into the queue
 - If $g(m) > g(n) + C_{nm}$
 - $g(m) = g(n) + C_{nm}$
 - end
- End Loop

Dijkstra's Algorithm

Pros and Cons of Dijkstra's Algorithm

- The good:
 - Complete and optimal
- The bad:
 - Can only see the cost accumulated so far (i.e. the uniform cost), thus exploring next state in every "direction"
 - No information about goal location

Search Heuristics

- Recall the heuristic introduced in **Greedy Best First Search**
- Overcome the shortcomings of uniform cost search by **inferring the least cost to goal** (i.e. goal cost)
- Designed for particular search problem
- Examples: Manhattan distance VS. Euclidean distance

A*: Dijkstra with a Heuristic

- Accumulated cost
 - $g(n)$: The current best estimates of the accumulated cost from the start state to node “n”
- Heuristic
 - $h(n)$: The **estimated least cost** from node n to goal state (i.e. goal cost)
- The least estimated cost from start state to goal state passing through node “n” is $f(n) = g(n) + h(n)$
- Strategy: expand the node with **cheapest $f(n) = g(n) + h(n)$**
 - Update the accumulated costs $g(m)$ for all unexpanded neighbors “m” of node “n”
 - A node that has been expanded is guaranteed to have the smallest cost from the start state

A* Algorithm

- Maintain a **priority queue** to store all the nodes to be expanded
- The heuristic function $h(n)$ for all nodes are pre-defined
- The priority queue is initialized with the start state X_s
- Assign $g(X_s)=0$, and $g(n)=\text{infinite}$ for all other nodes in the graph
- Loop
 - If the queue is empty, return FALSE; break;
 - **Remove** the node "n" with the lowest $f(n)=g(n)+h(n)$ from the priority queue
 - Mark node "n" as **expanded**
 - If the node "n" is the goal state, return TRUE; break;
 - For all **unexpanded** neighbors "m" of node "n"
 - If $g(m) = \text{infinite}$
 - $g(m) = g(n) + C_{nm}$
 - Push node "m" into the queue
 - If $g(m) > g(n) + C_{nm}$
 - $g(m) = g(n) + C_{nm}$
 - end
- End Loop

Only difference comparing to
Dijkstra's algorithm

A* Example

A* Optimality

- What went wrong?
- For node A: actual least cost to goal (i.e. goal cost) < estimated least cost to goal (i.e. heuristic)
- We need the estimate to be **less than** actual least cost to goal (i.e. goal cost) **for all nodes**!

Admissible Heuristics

- A Heuristic h is **admissible** (optimistic) if:
 - $h(n) \leq h^*(n)$ for all node " n ", where $h^*(n)$ is the true least cost to goal from node " n "
- If the heuristic is admissible, the A* search is optimal
- Coming up with admissible heuristics is most of what's involved in using A* in practice.
- Example:

Heuristic Design

An admissible heuristic function has to be designed case by case.

- Euclidean Distance
- Manhattan Distance

Is Euclidean distance (L2 norm) admissible?

Always

Is Manhattan distance (L1 norm) admissible?

Depends

Is L^∞ norm distance admissible?

Always

Is 0 distance admissible?

Always

Dijkstra' s VS A*

- Dijkstra' s algorithm expanded in all directions

- A* expands mainly towards the goal, but does not hedge its bets to ensure optimality

Sub-optimal Solution

What if we intend to use an over-estimate heuristic?

- Suboptimal path
- Faster

Weighted A*:

Expands states based on $f = g + \epsilon h, \epsilon > 1$ = bias towards states that are closer to goal.

- Weighted A* Search:

- Optimality vs. speed
- ϵ -suboptimal:
 $\text{cost}(\text{solution}) \leq \epsilon \text{cost}(\text{optimal solution})$
- It can be orders of magnitude faster than A*

Weighted A* -> Anytime A* -> ARA* -> D*

Beyond the scope of this course

Greedy Best First Search vs. Weighted A* vs. A*

$$f = a \cdot g + b \cdot h$$

Most Greedy

$$a = 0, b = 1$$

Tunable Greediness

$$a = 1, b = \varepsilon > 1$$

Optimal

$$a = 1, b = 1$$

Engineering Considerations

Example: Grid-based Path Search

How to represent grids as graphs?

Each cell is a node. Edges connect adjacent cells.

Common Choice!

4 connection

8 connection

Grid-based Path Search: Implementation

- Create a dense graph.
 - Link the occupancy status stored in the grid map.
 - Neighbors discovered by grid index.
 - Perform A* search.
-
- **Priority queue in C++**
 - `std::priority_queue`
 - `std::make_heap`
 - `std::multimap`

The Best Heuristic

- Recall:

- Is Euclidean distance (L2 norm) admissible?
- Is Manhattan distance (L1 norm) admissible?
- Is L_∞ norm distance admissible?
- Is 0 distance admissible?

They are useful, but none of them is the best choice, why?

Because none of them is **tight**.

Tight means how close they measure the true shortest distance.

Euclidean Heuristic

Why so many nodes expanded?

Because Euclidean distance is far from the **truly theoretical optimal solution**.

The Best Heuristic

How to get the **truly theoretical optimal solution?**

Fortunately, the grid map is highly structural.

- You don't need to search the path.
- It has the **closed-form solution!**

$$dx = \text{abs}(\text{node.x} - \text{goal.x})$$

$$dy = \text{abs}(\text{node.y} - \text{goal.y})$$

$$h = (dx + dy) + (\sqrt{2} - 1) * \min(dx, dy)$$

For 3D case, we also have a similar version of this.

Compare

Diagonal Heuristic

Tie Breaker

- Many paths have the same f value.
- No differences among them making them explored by A* equally.

- Manipulate the f value breaks the tie.
- Make same f values differ.
- Interfere h slightly.

$$h = h \times (1.0 + p)$$

$$p < \frac{\text{minimum cost of one step}}{\text{expected maximum path cost}}$$

Slightly breaks the admissibility of h , does it matter?

Tie Breaker

Core idea of tie breaker:

Find a preference among same cost paths

- When nodes having same f , compare their h .
- Add deterministic random numbers to the heuristic or edge costs (A hash of the coordinates).
- Prefer paths that are along the straight line from the starting point to the goal.

$$\begin{aligned}dx1 &= \text{abs}(\text{node}.x - \text{goal}.x) \\dy1 &= \text{abs}(\text{node}.y - \text{goal}.y) \\dx2 &= \text{abs}(\text{start}.x - \text{goal}.x) \\dy2 &= \text{abs}(\text{start}.y - \text{goal}.y) \\cross &= \text{abs}(dx1 \times dy2 - dx2 \times dy1) \\h &= h + cross \times 0.001\end{aligned}$$

- ... Many customized ways

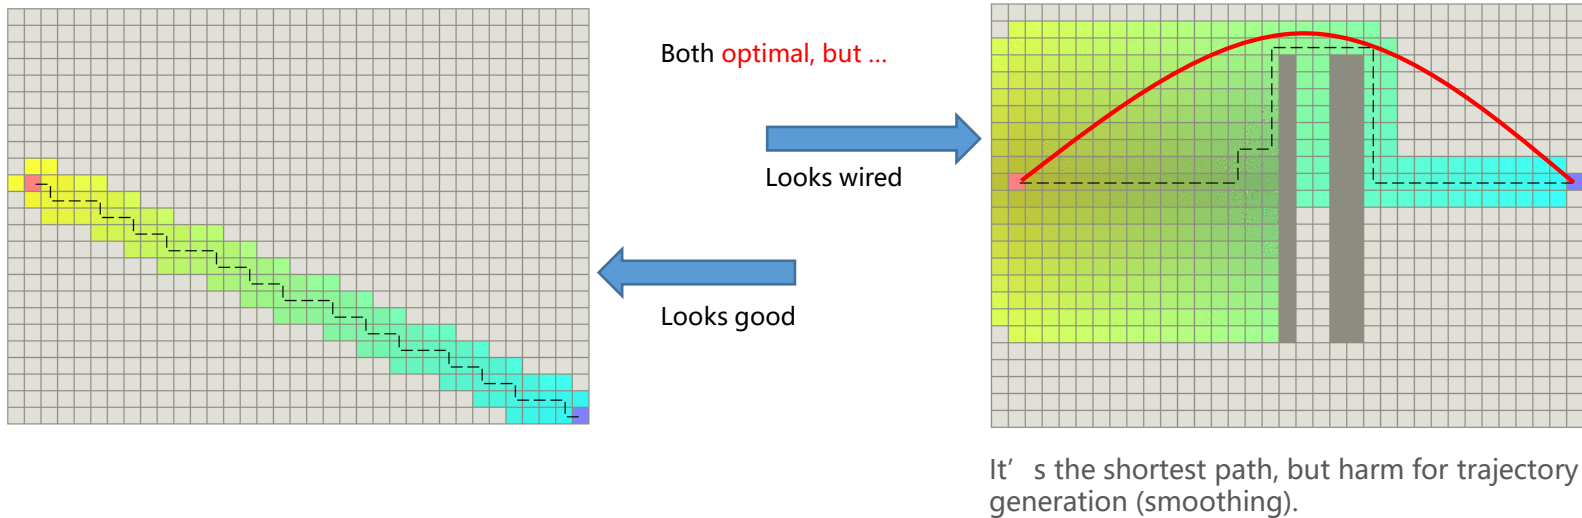

Better/other **tie breaker**?

Tie Breaker

- Prefer paths that are along the straight line from the starting point to the goal.

Or a systematic approach: **Jump Point Search (JPS)**

Jump Point Search

Algorithm Workflow

Jump Point Search

Core idea of JPS:

Find symmetry and break them.

A* explore all symmetric path.

JPS choose one path.

Grey node: Added in the Open List.

JPS explores intelligently, because it always looks ahead based on a rule.

Look Ahead Rule

straight

diagonal

Consider:

- current node x
- x 's expanded direction

Neighbor Pruning

- Gray nodes: **inferior neighbors**, when going to them, the path without x is cheaper. Discard.
- White nodes: **natural neighbors**.
- We only need to consider natural neighbors when expand the search.

Forced Neighbors

- There is obstacle adjacent to x
- Red nodes are **forced neighbors**.
- A cheaper path from x 's parent to them is blocked by obstacle.

Jumping Rules

Jumping Straight

Look Ahead Rule

Jumping Diagonally

- Recursively apply **straight** pruning rule and identify y as a **jump point successor** of x. This node is interesting because it has a neighbor z that cannot be reached optimally except by a path that visits x then y.
- Recursively apply the **diagonal pruning** rule and identify y as a **jump point successor** of x.
- Before each diagonal step we first recurse straight. Only if both straight recursions fail to identify a jump point do we step diagonally again.
- Node w, a forced neighbor of x, is expanded as normal. (also push into the open list, the **priority queue**)

Jump Point Search

- Expand horizontally and vertically.
- Both jumps end in obstacles.
- Move diagonally.

Jump Point Search

- Expand horizontally and vertically.
- Both jumps end in obstacles.
- Move diagonally.

Jump Point Search

- Expand horizontally and vertically.
- Both expansions end in obstacles.
- Move diagonally.

Jump Point Search

- **Remember:** you can only jump straight or diagonally; never piecewise jump
- Vertically expansion end in obstacle.
- Right-ward expansion finds a node with a **forced neighbor**.

Recall the rule

1		3
4	x	5
6	7	8

So we have

1	2	3
4	x	5
6		8

Jump Point Search

- Now this node is of interested.
- Put it to open list.

Jump Point Search

Recall A*'s pseudo-code, JPS's is all the same!

- Maintain a priority queue to store all the nodes to be expanded
- The heuristic function $h(n)$ for all nodes are pre-defined
- The priority queue is initialized with the start state X_s
- Assign $g(X_s)=0$, and $g(n)=\text{infinite}$ for all other nodes in the graph
- Loop
 - If the queue is empty, return FALSE; break;
 - Remove the node "n" with the lowest $f(n)=g(n)+h(n)$ from the priority queue
 - Mark node "n" as expanded
 - If the node "n" is the goal state, return TRUE; break;
 - For all unexpanded neighbors m of node "n"
 - If $g(m) = \text{infinite}$
 - $g(m) = g(n) + C_{nm}$
 - Push node "m" into the queue
 - If $g(m) > g(n) + C_{nm}$
 - $g(m) = g(n) + C_{nm}$
 - end
- End Loop

A*: "Geometric" neighbors

JPS: "Jumping" neighbors

Example

Jumping Example

Planning Case

Jumping Example

- Expand—> move diagonally
- Find a critical node finally, add it into open list.
- Pop it (the only one) from the open list.
- Expand vertically, end at obstacles.

Jumping Example

- Expand horizontally, meets a node with a forced neighbor.
- Add it to open list

Recall the rule

1		3
4	x	5
6	7	8

So we have

1	2	3
4	x	5
6		8

Jumping Example

- Expand diagonally, expand, find nothing.
- Finish the expansion of the current node.

Jumping Example

- Examine the “new best” node in the open list.
- Expand horizontally.
- Finds nothing.

Remember the rule

1	2	3
4 → x	5	
6		8

Jumping Example

- Move diagonally.
- Expand along vertical and horizontal first.

Jumping Example

- Finds nothing.
- Move diagonally.

Jumping Example

- Expand horizontally and vertically.
- Finds the goal. Equally interested as finding a node with a forced neighbor.
- Add this node to open list.
- Finish the expand of the current node (No naturally neighbors left).
- Pop it out of the open list.

Jumping Example

- Examine the “new best” node in the open list.
- Expand horizontally (nowhere), and vertically (finds the goal).
- The end.

Jumping Example

Final Path

Example

Planning Dynamically Feasible Trajectories for Quadrotors using Safe Flight Corridors in 3-D Complex Environments,
Sikang Liu, RAL 2017

<https://github.com/KumarRobotics/jps3d>

Is JPS always better?

Maze-like environments

JPS

A*

Do more tests by yourself!

Thanks: <http://qiao.github.io/PathFinding.js/visual/>

Is JPS always better?

- This is a simple example saying “No.”
- This case may commonly occur in robot navigation.
- Robot with limited FOV, but a global map/local map.

Conclusion:

- Most time, especially in complex environments, JPS is better, but far away from “always”. Why?
- JPS reduces the number of nodes in **Open List**, but increases the number of **status query**.
- You can try JPS in Homework 2.
- **JPS's limitation**: only applicable to uniform grid map.

Homework

Testing Environment

Matlab

Basic

C++

Advance

Assignment: Basic

- This project work will focus on path finding and obstacle avoidance in a 2D grid map.
- A 2D grid map is generated randomly every time the Project is run, which contains the obstacles, start point and target point locations will be provided. You can also change the probability of obstacles in the map in `obstacle_map.m`
- You need to implement a 2D A* path search method to plan an optimal path with safety guarantee.

Assignment: Advance

- I highly suggest you implement Dijkstra/A* with C++/ROS.
- Complex 3d map can be generated randomly. The sparsity of obstacles in this map is tunable.
- An implementation of JPS is also provided. Comparisons can be made between A* and JPS in different map set-up.

Thanks for Listening!
